13. ABSTRACT *(Maximum 200 words)*

The use of laser light for targeting devices and weapons has sharply increased the likelihood that aircrew and support personnel will be exposed during operations. The increased potential for exposure of humans to laser light highlights the need for scientifically-based safety standards for laser exposure at the ultrashort pulse lengths. Current safety standards are largely extrapolations of exposure limits at longer pulse lengths using a minimal visible lesion endpoint in the Rhesus monkey retinal model. A non-animal model for assessing laser-light damage to tissue, particularly human, is quite desirous for obvious scientific, political, and fiduciary reasons. We assessed the sublethal insult to human cells using a tissue culture system for specific genes that have been shown to be important in several biological processes that could lead to cancer or cell death. Using the CAT-Tox (L) assay, it appears that 910 and 455 nm, femtosecond pulses of laser light is sensed and induces several stress response genes. Both wavelengths induced the xenobiotic receptor element in a roughly dose dependent fashion at 48 hours post exposure; while also inducing other genes to yield a genetic expression fingerprint unique to the exposure parameters. This approach provides insight into a more global methodology for characterizing environmental stressors via genetic profiling.

ABSTRACT

The use of laser light for targeting devices and weapons has sharply increased the likelihood that aircrew and support personnel will be exposed during operations. The increased potential for exposure of humans to laser light highlights the need for scientifically-based safety standards for laser exposure at the ultrashort pulse lengths. Current safety standards are largely extrapolations of exposure limits at longer pulse lengths using a minimal visible lesion endpoint in the Rhesus monkey retinal model. A non-animal model for assessing laser-light damage to tissue, particularly human, is quite desirous for obvious scientific, political, and fiduciary reasons. We assessed the sublethal insult to human cells using a tissue culture system for specific genes that have been shown to be important in several biological processes that could lead to cancer or cell death. Using the CAT-Tox (L) assay, it appears that 910 and 455 nm, femtosecond pulses of laser light are sensed and induces several stress response genes. Both wavelengths induced the xenobiotic receptor element in a roughly dose-dependent fashion at 48 hours post-exposure; while also inducing other genes to yield a genetic expression fingerprint unique to the exposure parameters. This approach provides insight into a more global methodology for characterizing environmental stressors via genetic profiling.

INTRODUCTION

Military and civilian technology of the 21st century will increasingly rely on the use of laser light, and thus increase the chances that personnel will be intentionally or accidentally optically exposed. Current safety standards for laser light exposure to the eye are based largely on whole animal minimal visible retinal lesion studies[1], and do not take into account the possibility of subtle sub-lethal long term effects which may become manifest long after acute treatment. Additionally, current treatment of laser-exposed patients is concluded after visible lesions abate. Furthermore, there is no thorough scientific understanding of the laser-light damage mechanisms at the cell and molecular level. Therefore, it would be of great benefit to develop, validate, and genetically engineer a tissue culture based methodology with cell lines possessing qualitatively and quantitatively sensitive damage-induced reporter gene systems.

Such cell lines would provide an *in vitro* model of the laser-tissue interaction in the eye, which could serve as the test bed for a variety of experiments leading to the development of sub-lethal laser exposure safety limits. The outermost layer of the retina, the Retinal Pigment

Epithelium (RPE), plays a critical role in the physiology of the underlying photoreceptors(2,3). In order to engineer a retinal pigment epithelial cell line, we must first investigate the generic genetic response, if any, of human cells to laser-light exposure. In this experiment, using a battery of 13 known damage-induced reporter genes, we assessed the genetic response of human cells grown in a tissue culture format to laser-light insult. The development of a non-animal model for assessing laser-light damage to living tissue, particularly human, is quite desirous for obvious scientific, socio-political and fiduciary reasons and we believe that it has become technologically possible.

MATERIALS AND METHODS

General description:

The purpose of this study was to investigate the gene activity induced in human cells by high energy, ultrashort pulse laser-light exposure. The CAT-Tox (L) assay, developed by Xenometrix, Inc. (Boulder, CO), is designed to detect transcriptional responses to a variety of compounds including DNA damaging agents and oxidative stressors in human liver cells. This gene profile assay uses a human liver cell line (HepG2) and 13 mammalian gene reporter constructs driving expression of the chloramphenicol acetyltransferase (CAT) reporter gene. This assay was selected because it was technically appropriate, commercially available and relatively easy to adapt to laser bioeffects investigation.

In this particular series of experiments, a battery of 13 human stress response genes in reporter gene constructs known to be induced by various types of cellular stress or damage were used to assess the bioeffects of laser light exposure on human cells at the cell and molecular level. This mammalian gene profile assay is capable of measuring differential gene expression in the human hepatoma cell line, HepG2. The thirteen different recombinant human liver cell lines were generated by creating stable transfectants of different mammalian promoter-CAT gene fusions. The activity of a given promoter is quantified simply by the accumulation of CAT protein, measured using a standard CAT ELISA (Enzyme Linked Immuno-Sorbent Assay) detection system.

A broad range of promoters responsive to DNA damage, heavy metal ions, protein denaturants, aromatic hydrocarbons, retinoids, and changes in intracellular cyclic AMP levels have been included in the assay. In some cases specific response elements are monitored, permitting fine analysis of stress-regulated gene expression.

The gene profile assay [CAT-Tox (L)] has been designed to use a 96-well microtiter plate format. This system gives simultaneous dose-response information at five different exposures for the 13 recombinant cell lines. The assay yields results in 24 to 48 hours. The results are displayed in histogram form as a XenoMatrix[TM]. The assay also includes the parental HepG2 line for the measurement of cytotoxicity. The assay can distinguish subtle differences among closely related effects, and can indicate molecular mechanisms of sub-lethal cellular injury.

2

<u>Exposure</u>:

For the CAT-Tox (L) assays the cells were divided into the following groups. Two rows of cells per 96-well plate were controls (non-lased cells). The remainder of the rows were exposed to various energies of laser-light using the 910 nm (nanometer) or 455 nm wavelength of a Ti-Saphire laser (Coherent, Mira, model 900F) at a pulse width of 111 or 58.1 femtoseconds (fs), respectively, pulsing at 76 MHz. The beam was shaped to as uniformly as possible fill the bottom of the well. The lowest exposure was 1.58 nJ (nanoJoules)/pulse delivering 120 mJ (milliJoules) of energy to the surface of the tissue culture media in the well. The highest dosage was 30 seconds (s) at 12.5 nJ per pulse at 76 MHz yielding 28,500 mJ on target. Three of the exposures were assayed at 24 hours and two at 48 hours post-exposure. All pulses were delivered to the surface of 50 microliters of growth media in a 6 mm well in 96-well polystyrene (Falcon, 3072) plates containing a confluent monolayer of cells on the bottom of the well. Table 1 indicates the 910 nm exposure and assay regimen for the data displayed in Figures 1 and 2. Table 2 indicates the 455 nm exposure and assay regimen for the data displayed in Figures 3 and 4.

Table 1: 910 nm laser light exposures.

Treatment	Exposure Duration (s)	Pulse Energy (nJ)	Total Incident Energy (mJ)	Post Exposure Assay Time (hr)
A (control)	0	0	0	24/48
B	10	11.5	8500	24
C	30	11.5	25500	24
D	1	12.5	950	48
E	10	12.5	9500	48
F	30	12.5	28500	48

Table 2: 455 nm laser light exposures.

Treatment	Exposure Duration (s)	Pulse Energy (nJ)	Total Incident Energy (mJ)	Post Exposure Assay Time (hr)
A (control)	0	0	0	24/48
B	10	1.45	1100	24
C	30	1.45	3300	24
D	1	1.58	120	48
E	10	1.58	1200	48
F	30	1.58	3600	48

<u>Gene profile assay</u>:

We adapted the manufacturer's protocol to assess the effects of laser-light exposure and they were done in triplicate. The assay involved 13 stably transfected human liver cell lines, each containing a unique stress-responsive promoter or response element fused to the CAT reporter gene. In each genetically induced cell line, the CAT reporter gene was transcribed and subsequently translated. CAT production is detected by an ELISA methodology yielding a

quantitative measure of the stress gene induction expressed as fold induction compared to the control. Those cell lines without CAT protein production will not show gene induction above the control (non-lased cells). One, triplicate gene profile assay was performed, using a human liver cell line (HepG2), and 13 mammalian gene reporter constructs driving expression of the CAT gene. The assay was performed with concurrent negative controls, and assayed separately with known positive control exposures. The assays performed within acceptable limits for both positive and negative controls.

Assay procedure: A shortened version of the assay protocol is as follows.
1. The 13 recombinant cell lines and the parental HepG2 cell line are plated, one row each, over two 96-well microtiter plates.
2. The cell lines are dosed at five exposures and incubated at 37°C, 5% CO_2 for 24 or 48 hrs.
3. After the post-exposure incubation period the cells are washed two times and lysed with a detergent based buffer to release total cellular protein.
4. An aliquot of the total protein is transferred to 96-well microtiter plates containing Bradford protein dye. Incubation of the protein with the protein dye creates a color change that can be measured at optical density $(OD)_{600}$. This reading serves as a normalization factor for total cellular protein from well to well in the assay.
5. The remaining cellular protein is transferred to 96-well plates containing polyclonal anti-CAT antibodies. A standard sandwich ELISA is performed and in the final step horseradish peroxidase catalyzes a color change reaction that can be measured at OD_{405}.
6. The parental HepG2 cell line that was dosed in the same manner as the 13 recombinant lines is used to perform a 3-(4,5-dimethylthiazol-2-yl)-2,5 diphenyltetrazolium bromide (MTT) mitochondrial reduction-based cellular viability assay. The results of this assay can be monitored at OD_{550}.
7. Xenometrix software uses the OD_{600} and OD_{405} readings to calculate the transcriptional fold induction for each recombinant cell line at each test exposure. The software also converts the OD_{550} to cellular viability percentages.

All plates containing the control and experimental cells were measured in an automated microplate reader (Bio-Kinetics, EL312e) which read their optical density (endpoint of ELISA) as a measure of CAT production or gene expression. This data was then electronically transferred to a computer database and eventually tabulated in graphic form. Three trials were conducted and the results were averaged (graphically represented in Figures 1 and 3). The assay allowed us to gather qualitative (which genetic control elements were activated) and quantitative (fold induction) data.

Note that the mention of a gene's induction in the CAT-Tox assay actually represents the induction of its genetic control element present in the engineered cell line driving the reporter gene CAT. The level of CAT expression has been shown to be indicative of the level of wildtype gene expression regulated by the same genetic control element under the same conditions (Xenometrix). Therefore, we use the fold induction of the control element to represent the wildtype gene's expression level in our discussions.

4

DATA ANALYSIS

Cell viability:

Cell viability is calculated as the percent of the cells surviving at the assay time in the dosed samples versus the no dose control. In the gene profile assay, viabilities are recorded based on the results of MTT viability assays performed concurrent with the assay shown as the shaded area along the left wall of Figures 1 and 3.

Gene expression (fold induction) calculations:

Gene expression is measured as the fold induction. That is the fold (multiple) increase of a construct at concentration n is determined by dividing the construct activity at each dose, $n(i)$, by the activity at the zero dose. The levels of gene induction are expressed as multiples of basal or background values (zero dose). In the gene profile assay, background activity values are normalized and represented as 1.0 fold induction.

Statistical analysis:

Unequal variance comparison t-tests and multiple comparison with a control case (The Dunnett test) are used to determine significance (at the $\alpha = 0.05$ level) of activity at each dose (the corresponding fold increase must be greater than 1.0). The unequal variance t-test is performed to test the null hypothesis for each concentration of a compound in comparison to the zero-dose control. The following formula is used for the t-tests:

Hypothesis: H_0:mean activity at dose i=mean activity at zero dose

H_1:mean activity at dose i>mean activity at zero dose

When $t > t_{a,v}$ at the $\alpha = 0.05$ significance level, H_0 is rejected and there exists a significant difference between the mean activity at dose i and the activity at the zero dose.

The unequal variance t-tests provide the analyses corresponding to the different dose levels versus the zero dose control comparisons. However, assuming each of the separate comparisons is performed at significant level α, each t-test is subject to a possible false positive ("type I") error rate equal to $100\alpha\%$. When multiple comparisons are conducted on the same set of data, this error rate applies to *each* comparison, and may be considerably inflated using simple t-test comparisons. To correct for this multiplicity, the test statistics must be adjusted to bring their experiment-wise error rates back to α. This is accomplished by incorporating simultaneous inferences on multiple comparisons. Thus we used the Dunnett..

The statistical analysis is performed through both the unequal variance t-test and Dunnett's test. The conclusive statistical significance is based on either of these tests demonstrating significance when the calculated fold induction is above 1.0. Statistical insignificance is a fold increase value

less than 1.0. At low levels of fold induction these tests are very conservative in determining statistical significance.

RESULTS

<u>Cell cytotoxicity</u>:

The cell viability portion of the assay are shown along the left wall on the graph on Figures 1 and 3 in percent viability. Figure 1 indicates that the parent cell line withstood pulses of 910 nm laser-light at or greater than 100% viability for nearly all exposures. But viability decreased markedly in the 455 nm exposures in a dose dependent fashion in the 24 hour assays while the 48 hour treatments (E and F) remained stable at approximately 80% survival as shown graphically on the left wall of Figure 3.

<u>Human stress gene induction</u>:

The controls in this experiment were the identical cell lines that were not exposed to the laser light beam. Appropriately, these lines did not show fold induction in the assay as seen in Figure 1 and 3, and are used as a baseline for the treated cells. One of the stress reporter-gene cell lines, XRE, showed a roughly dose-dependent induction by both wavelengths. GADD45*(4,5)*, NFkBRE*(6,7,8)* and HMTIIA*(9)* were also induced by both wavelengths in some treatments. While others, [RARE*(10,11)*, CRE*(12)* and GRP78*(13)*] were induced differentially by exposure to the different wavelengths and energies. Curiously, HSP70*(14,15,16)* seemed to be slightly down-regulated by both treatment regimens. The remaining constructs did not show any marked stress response.

Statistical analysis revealed (Figures 2 and 4), only XRE was genetically induced to a significant level by both wavelengths of laser light particularly when assayed 48 hours post-exposure. The 910 nm (Figure 2) treatments resulted in a significant although low-level induction of GRP78 in the 48 hour assays and one event of CRE induction at 48 hrs. The 455 nm treatments yielded significant inductions (Figure 4) of NFkBRE in the 48 hour assays in addition to XRE.

DATA INTERPRETATION

The results strongly indicate several important findings. First, that human cells, liver cells in this case, have the ability to "sense" ultrashort pulse high-energy laser light exposure. Secondly, human cells can respond to sublethal laser light insult using, at a minimum, some of the same stress response genes previously characterized in response to other cellular stressors. The nearly dose-dependent response exhibited in the XRE*(17)* constructs (approximately 3-5 fold inductions) is a particularly significant result. This promoter fusion responds to numerous highly mutagenic and carcenogenic componds. It is normally activated by the nuclear translocation of the Ah (aryl hydrocarbon) receptor. The Ah receptor-ligand complex then induces transcription by binding to the XRE in various protective genes such as GST Ya (glutathione S-transferase Ya subunit promoter)*(17)* and CYPIA1 (cytochrome P450 IA1 promoter)*(18)* neither of which were

induced in these experiments. The GADD45 construct activation, although below statistical significance yet consistent in both experiments, also indicates possible DNA damage, which could have profound implications to the safety standards for laser exposure, since this implies subtle long-term effects such as carcinogenesis. These results are also consistent with the findings of Leavitt, et.al(19). The NFkBRE, also inducible by DNA damage, was significantly induced in the 455 nm experiments with statistically significant indications in the 910 nm experiments. The gene is involved in the apoptosis regulatory pathway. Apoptosis is defined as programmed cell death or cell suicide. This finding is concordant with and possibly explains the "biological magnification" of retinal lesions non-existent at 1 hr post-exposure but present at 24 hours post-exposure. Low level RARE construct induction could signal DNA mutagenesis or other forms of aberrant gene activation. Retinoids are involved in numerous developmental pathways in humans. The GRP78 gene induction indicates possible heat shock and potential intracellular protein denaturation particularly in the endoplasmic reticulum compartment of the cell which is responsible for protein synthesis(13). Since the GRP78 gene was induced in the 48-hr assays and not in the 24-hour assays, it appears the cells were slow responding to the heat shock and was only induced in the cells treated with the 910 nm light which fits well into current damage hypotheses.

CONCLUSION

These results will point us in the proper direction for development of an immortalized RPE cell line genetically engineered with appropriate CAT-producing stress reporter-gene constructs. At this juncture we can say that any *in vitro* laser tissue damage assessment system should include
DNA damage constructs. Cellular genes such as those coded for by GRP78, XRE, RARE, and the apoptotic gene, NFkBRE, should also be considered for incorporation. Such constructs will provide a qualitative basis as well as a quantitative measure for damage in the retinal cells, so that more sophisticated understanding of laser induced damage at the cell and molecular level can be elucidated.

From a more global perspective, these findings provide a "proof of concept" that gene profiling technologies can be extremely efficacious in approaching the problem of laser-tissue interaction from the biological perspective. Gene profiling can provide insight into the type and degree of laser induced damage at the cell and molecular level as well as the damage thresholds for induction of repair metabolism or promotion of apoptosis or necrosis. The medical ramifications of these technologies are obvious in the context of prophylaxis and treatment.
